
The bold line is one reconstruction per tree (DP trees: the most probable path; trees of the probabilistic matcher: the most representative draw); each realization takes a random posterior draw per tree. Before census 7 (2010) the draws split more stem histories into two stems than the exported reconstruction does (stems: +0.5% in DP trees, +2.2% in matcher trees). A split turns one continuing stem into one that dies (its basal area counts as Loss) and a new one (its basal area counts as Gain); Growth loses only that stem's growth, and the net change stays the same. MC median minus exported value, in % of the exported value: Gain +3.0% to +6.1%, Loss −0.6% to −0.3% (negative: a larger loss), Growth −0.1% to +0.1%. Trees are drawn independently, so their random differences cancel and the ribbon is narrow; a shift shared by many trees adds up and falls outside it. From census 7 on, every stem is tagged and the two agree.
